Abstract. We propose four different mechanisms responsible for paramagnetic or diamagnetic persistent currents in normal metal rings and determine the circumstances for change of the current from paramagnetic to diamagnetic ones and *vice versa*. It might qualitatively reproduce the experimental results of Bluhm et al. (Phys. Rev. Lett. 102, 136802 (2009)).

1. Introduction

In the absence of an applied voltage, an induced electrical current rapidly decays due to dissipation processes. In normal (not superconducting) metal rings it typically dies out within the relaxation time of order 10^{-13} s. However, if a radius of the ring is small enough (below microns) and temperature of the system is below 1 K, quantum effects start to play a distinct role. Under right circumstances electrons in the ring are able to preserve its coherence which in turn results in the persistent (dissipationless) current induced by the static applied magnetic field.

The existence of persistent currents in metallic rings was predicted by Hund in 1938 [1]. More than 30 years later Bloch [2] and Kulik [3] confirmed this prediction by means of quantum-mechanical models. The strong interest in physics of mesoscopic rings arose after the 1983 paper [4] where the authors showed that persistent currents could flow even in the presence of disorder. Experiments on persistent currents have produced a number of confusing results in apparent contradiction with theory and even amongst the experiments themselves (e.g. the response of rings was 10-200 larger than theoretically predicted) [5]. We could observe persistent controversy on persistent currents for nearly twenty years. Recently, two groups [6, 7] have developed new different techniques which allow to make measurements a full order of magnitude more precise than any previous attempts. Both experiments confirm to a high degree the physics theory regarding the behavior of persistent currents. The group of K. Moler [6] has employed a scanning

technique (a SQUID microscope) and measured the magnetic response of 33 individual mesoscopic gold rings. Each ring was scanned individually, unlike past experiments on persistent currents conducted by other groups. In total the rings were scanned approximately 10 million times. The team of J. Harris [7] has developed an alternative measurement scheme. The aluminum rings have been deposited on a cantilever used as a torque magnetometer whose vibration frequency can be precisely monitored. From the frequency shift caused by the magnetic flux, the researchers could deduce the current with a precision of two orders of magnitude greater than it was possible in the past. They have studied several different cantilevers decorated with a single aluminium ring or arrays of hundreds or thousands of identical aluminium rings. The rings on different cantilevers had radii of 308-793 nanometers.

Persistent currents are highly sensitive to a variety of factors. It is clearly visible in experimental data shown in panel (b) of Fig. 2 in Ref. [6]: for nominally identical samples the observed response is paramagnetic (e.g. for the ring 1) or diamagnetic (e.g. for the ring 2). Here, we propose several possible mechanisms for controlling the response of the metallic mesoscopic rings and determine the conditions for which the transition from paramagnetic to diamagnetic current is able to occur.

The paper is arranged as follows. In the section 2, we start with the presentation of the model for the flux dynamics in the rings. Next, in the section 3, we identify the operating conditions on which similar rings can exhibit opposite responses. We finalize the paper with conclusions in the section 4.

2. Model for flux dynamics of mesoscopic rings

At low temperature, small normal metal rings threaded by a magnetic flux can display persistent and non-dissipative currents carried by phase-coherent electrons. The circumference of the ring should be smaller than the electrons phase coherence length. This typically limits the sample size to below micrometers and the temperature to below 1 K. However, at temperature $T > 0$, a part of electrons loses its phase-coherence due to thermal fluctuations and constitutes a dissipative Ohmic current associated with the resistance R . The actual magnetic flux ϕ induced by the current flowing in the ring is given by the relation

$$\phi = \phi_e + LI, \quad (1)$$

where ϕ_e is the magnetic flux generated by the external constant magnetic field, I denotes the total current flowing in the ring and L stands for the self-inductance of the ring. Dynamics of the magnetic flux ϕ in such a system is modeled by the dimensionless Langevin-type equation [8]

$$\frac{dx}{ds} = -\frac{dV(x)}{dx} + \sqrt{2D_\lambda(x)} \Gamma(t), \quad (2)$$

where $x = \phi/\phi_0$ is the rescaled magnetic flux and $\phi_0 = h/2e$ is the flux quantum. The rescaled time $s = t/\tau_0$, where the characteristic time $\tau_0 = L/R$ is the inductive time of

the ring. For a typical mesoscopic ring, L/R is in the picosecond range. The function

$$V(x) = \frac{1}{2}(x - x_e)^2 + B(x), \quad (3)$$

where $x_e = \phi_e/\phi_0$ and [8]

$$B(x) = \alpha \sum_{n=1}^{\infty} \frac{A_n(T_0)}{2n\pi} \cos(2n\pi x) [p + (-1)^n(1-p)], \quad (4)$$

where $\alpha = LI_0/\phi_0$ and I_0 is the maximal persistent current at zero temperature. In the mechanical context, $V(x)$ could be interpreted as an effective potential. The temperature dependent amplitudes $A_n(T_0)$ are determined by the relation [9]

$$A_n(T_0) = \frac{4T_0}{\pi} \frac{\exp(-nT_0)}{1 - \exp(-2nT_0)} \quad (5)$$

with the dimensionless temperature $T_0 = T/T^*$, where the characteristic temperature T^* is proportional to the energy gap Δ_F at the Fermi surface. The persistent current strongly depends on the parity of the number of coherent electrons. It is taken into account by assigning the probability p of an even number of the coherent electrons. Then the corresponding probability of an odd number of the coherent electrons is given by $1 - p$.

Thermal equilibrium fluctuations are modeled by δ -correlated Gaussian white noise $\Gamma(t)$ of zero mean. Classically this situation holds true in many cases. When temperature is lowered, however, the quantum nature of thermal fluctuations becomes important and starts to play a role. Therefore the standard diffusion coefficient $D_0 = k_B T/R$ (k_B denotes the Boltzmann constant) is modified due to quantum effects like tunnelling, quantum reflections and purely quantum fluctuations [10, 11, 12]. The modified diffusion coefficient D_λ assumes the form [11, 8]

$$D_\lambda(x) = \frac{\beta^{-1}}{1 - \lambda\beta V''(x)} \quad (6)$$

with $\beta^{-1} = k_B T/2E_m = k_0 T_0$, the elementary magnetic flux energy $E_m = \phi_0^2/2L$ and $k_0 = k_B T^*/2E_m$ is the ratio of two characteristic energies. The prime denotes differentiation with respect to x . The dimensionless quantum correction parameter [10]

$$\lambda = \lambda_0 \left[\gamma + \Psi \left(1 + \frac{\epsilon}{T_0} \right) \right], \quad \lambda_0 = \frac{\hbar R}{\pi \phi_0^2}, \quad \epsilon = \frac{\hbar/2\pi C R}{k_B T^*}, \quad (7)$$

where the psi function $\Psi(z)$ is the logarithmic derivative of the Gamma function, $\gamma \simeq 0.5772$ is the Euler gamma constant and C is capacitance of the system related to charging effects. The parameter λ characterizes quantum corrections to classical thermal fluctuations and can be formulated as the difference between quantum and classical fluctuations of the dimensionless flux,

$$\lambda = \langle x^2 \rangle_q - \langle x^2 \rangle_c \quad (8)$$

where $\langle \cdot \rangle$ denotes thermal equilibrium average, the subscripts q and c refer to quantum and classical cases, respectively. Let us remember that the diffusion coefficient $D_\lambda(x)$ cannot be negative and therefore the parameter λ has to be chosen small enough to

ensure its non-negativeness for any argument. Because in Eq. (2) the noise term contains the multiplicative white noise $\Gamma(t)$, it is important to stress that Eq. (2) has to be interpreted in the Ito sense [13]. Therefore the corresponding Fokker–Planck equation for the time evolution of the probability density $P(x, t)$ reads [13]

$$\frac{\partial}{\partial t}P(x, t) = \frac{\partial}{\partial x} \left[\frac{dV(x)}{dx} P(x, t) \right] + \frac{\partial^2}{\partial x^2} [D_\lambda(x) P(x, t)]. \quad (9)$$

The average stationary dimensionless current i flowing in the ring can be calculated from Eq. (1):

$$i = \langle x \rangle - x_e, \quad i = \langle I \rangle L / \phi_0 \quad (10)$$

and the average stationary magnetic flux $\langle x \rangle$ is calculated from the relation

$$\langle x \rangle = \int_{-\infty}^{\infty} x P(x) dx, \quad (11)$$

where $P(x) = \lim_{t \rightarrow \infty} P(x, t)$ is a stationary probability density being a solution of the Fokker–Planck equation (9) for $\partial P(x, t) / \partial t = 0$ and zero stationary probability current. It has the form

$$P(x) = N_0 D_\lambda^{-1}(x) \exp[-\Psi_\lambda(x)], \quad (12)$$

where N_0 is the normalization constant and the generalized thermodynamic potential $\Psi_\lambda(x)$ reads

$$\Psi_\lambda(x) = \int \frac{dV(x)}{dx} D_\lambda^{-1}(x) dx = \beta V(x) - \frac{1}{2} \lambda \beta^2 [V'(x)]^2. \quad (13)$$

In the case when thermal fluctuations can be treated classically, i.e. when $\lambda = 0$, the stationary state $P(x)$ is described by the Boltzmann distribution. When thermal fluctuations have to be considered as quantum fluctuations, the stationary state is still a thermal equilibrium state but now described by the non-Boltzmann distribution (12) with the x -dependence of the diffusion coefficient $D_\lambda(x)$.

3. Current–flux characteristics

We are interested in the current–flux characteristics, i.e. in dependence of the stationary current $i = i(x_e)$ on the applied magnetic flux x_e . To this aim we exploit Eqs. (10)–(13). Note that the external flux x_e enters Eq. (10) and the remaining equations via the potential (3) which occurs both in the diffusion function $D_\lambda(x)$ and the generalized thermodynamical potential $\Psi_\lambda(x)$. Because the persistent current is a periodic function of the magnetic flux, we consider the current–flux characteristics on the unit interval of x_e . We present four visually similar sets of the current–flux characteristics with various set-ups to demonstrate sensitivity of the persistent currents to some subtle effects. It could explain the different response of the nominally identical metal rings to the magnetic flux presented in the recent experimental work [6]. The measured persistent current of 15 nominally identical rings with radius $R = 0.67 \mu\text{m}$ exhibits both the paramagnetic and diamagnetic response. In panel (b) of Fig. 2 in Ref.[6], one can

Figure 1. (color online) The stationary averaged velocity vs the external magnetic flux x_e . In the panel (a) we show current–flux characteristics in the classical regime for three different temperatures $T_0 = 0.6, 0.6423, 0.7$. Panel (b) presents also the classical regime for three different structure constants $k_0 = 0.09, 0.1052, 0.12$. Panel (c) exhibits again the persistent current for ring working in the classical regime for three values of the probability $p = 0.4, 0.455, 0.5$ of an even number of coherent electrons in the ring. Finally panel (d) reveals the influence of the quantum parameter $\lambda_0 = 0$ (indicating classical regime), $0.00161, 0.002$ (quantum regime). Blue (solid) lines mark the paramagnetic response to the external stimulus, green (dashed) lines denote the situation where the magnetic susceptibility is zero and finally red (dashed–dotted) lines indicate the diamagnetic susceptibility of the normal metal mesoring around zero external magnetic flux (see insets for details). The parameters not given explicitly are set as follows: $T = 0.5$, $p = 0.48$, $k = 0.08$, $\alpha = 0.1$.

easily notice that in the linear response regime, i.e. for values of the external flux close to zero, the susceptibility defined as the ratio of the average persistent current to the external flux has sometimes positive slope indicating the paramagnetic current (see the current for the rings 1, 3, 4, 10, 11, 12, 15 in Fig. 2(b) in [6]) and sometimes negative slope exhibiting the diamagnetic response (see the current for the rings 2, 5, 6, 7, 8, 9, 13, 14 in Fig. 2(b) in [6]).

Figure 1 illustrate possible current–flux characteristics. All parameters are chosen arbitrarily as we don’t aim to compare our results with the experimental data. The goal

of this work is rather to constitute possible mechanisms responsible for diamagnetic or paramagnetic responses. Nevertheless, all curves corresponding to the paramagnetic currents (blue solid lines) in all panels look very similar to the experimental curve shown in figure S6(A) in the Supporting Online Material [14] of the paper [7].

In the panel (a) we depict the current–flux characteristics in the regime of classical thermal fluctuations (i.e. when $\lambda = 0$) for three different temperatures. For the lowest temperature $T_0 = 0.6$ (blue solid line) the situation reveals the paramagnetic response of the ring to the applied magnetic flux. For the higher temperature $T_0 = 0.7$ (red dashed–dotted line) the response is diamagnetic. The cross–temperature below which the response is paramagnetic and above which is diamagnetic was recognized numerically at the value of $T_0^C = 0.6423$ (see green dashed line and the inset of the panel (a) for details).

Panel (b) presents the ring reaction to the external stimulus for three values of the structure parameter $k_0 = k_B T^*/2E_m$. It stands for the ratio of the two characteristic energies, the thermal energy $k_B T^*/2$ to the magnetic energy $E_m = \phi_0^2/2L$. It is instructive to define k_0 in the alternative way as $k_0 = LI_0/\phi_0$. At the value of $k_0 = 0.09$ the response is paramagnetic (blue solid line), for $k_0 = 0.12$ it is diamagnetic (red dashed–dotted line) and again we have numerically identified the cross–value at the level of $k_0^C = 0.1052$ (green dashed line). We note that the ratio of two parameters $r_\alpha = \alpha/k_0 = i_0/I_0 \sim l_e/l$ describes the physical properties of the metal ring [15]. Here l_e is the elastic mean free path of the electron in the ring and l stands for the circumference of the ring. For the multichannel rings the above ratio is greater than one for the ballistic regime and smaller than one in the diffusive one. In the presented collection of the parameters the cross–value of the para– to – diamagnetic response lies slightly below the value of unity, i.e. at $r_\alpha^C \simeq 0.95$. It means that this border value lies in the diffusive regime and all rings designated by the higher values of k_0 showing the diamagnetic susceptibility will also lie in the same diffusive regime.

It is well known that the most straightforward way of turning the susceptibility from diamagnetic to paramagnetic is to change the probability p of an even number of coherent electrons in the ring. In the panel (c) we present the current for three different rings with probabilities $p = 0.5$ (blue solid line), 0.455 (green dashed line) and 0.5 (red dashed–dotted line) exhibiting the paramagnetic, zero and diamagnetic susceptibility, respectively.

In the last panel (d) we focus on the influence of quantumness of thermal fluctuations on persistent currents. The comparison of the classical thermal fluctuations with $\lambda_0 = 0$ and corresponding paramagnetic current (blue solid line) with two values of the non–zero quantum noise parameter $\lambda_0^C = 0.00161$ exhibiting zero magnetic susceptibility (green dashed line) and $\lambda_0 = 0.002$ with diamagnetic response (red dashed–dotted line) is presented. As shown, the sign of the current in the vicinity of zero magnetic field can be easily affected by small perturbation of the quantum correction parameter λ .

4. Conclusions

We have proposed four various mechanisms that can lead to either diamagnetic or paramagnetic currents in the metal rings. Two of them are related to the physical properties of the metal rings. These are the structure parameter k_0 together with the probability p of an even number of coherent electrons in the ring. Another two can be adjusted by tuning the temperature of the system. In the experiment [7], the temperature uncertainty is 7% [14]. In all presented cases, the small change of the control parameter causes the reversal of the susceptibility - from paramagnetic to diamagnetic ones or *vice versa*. In the nowadays experiments on the mesoscopic rings it is impossible to justify which system parameters are responsible for the observed responses. The fact that the scientists are able to perform the measurements on single separated rings is a great success and a milestone in the present state-of-the-art. In the near future the experimental physicists will be able to prepare experiments in the desired and more precise conditions and then our findings might be tested.
